Dynamic Response to Road Excitation and Noise Reduction

Weiji Wang University of Sussex, Brighton, United Kingdom BN1 9QT

w.j.wang@sussex.ac.uk

Summary

The structural response to the impact generates structure borne noise as part of pollution to the environment. To reduce the wheel noise can be achieved by attenuating the intensity of structural vibration. Tyred wheel dynamic response to road excitation during rolling has been simulated using finite element modelling in a graphical programming environment. The relationship between the noise generation energy of wheel and damping is investigated. It is proposed to reduce the noise by increasing the damping in the tyre structure. The effectiveness has been demonstrated by the simulation result.

□ The actual contact to ground is an area and the contact edges are subject to continuous impacts during the rolling.

□ Structural response to the impact generates structure borne noise as part of pollution to the environment.

□ To reduce the wheel noise can be achieved by attenuating the intensity of structural vibration.

□ Tyre vibration reduced by damping material is simulated.

□ The effectiveness of noise reduction is demonstrated by the simulation result.

Introduction

A major part of noise of fast travelling vehicle on road is generated from the tyre due to impact between the tyre contact area and road surface.

 \Box One of the rubber tyre functions is to isolate the vibration excitation caused by the road roughness for the rider.

□ Fast rolling wheel generates noise to all its surroundings through the air.

□ Due to main target for tyre research and development have been the road gripping durability and safety, significant measures taken to reduce the noise has been limited so far.

Introduction

 \Box A typical existing product example includes that an acoustic damping sheet is formulated for maximum damping efficiency over a broad frequency and temperature range with easy peel and stick features.

□ Tests show that the absorption can be from 13 dB to 42 dB from frequency 100Hz to 5000Hz. The higher the frequency, the more effective. Therefore, to use damping material to reduce tyre rolling noise becomes a hope for road noise solution.

This paper focuses on the simulation of vibrating wheel using finite element model in graphical dynamics environment, and how the vibrating energy is dissipated by increasing the damping in the tyre structure.

□ For better understanding of tyre wheel behaviour, displaying the dynamic characteristics is realised in MATLAB SIMULINK environment, graphically presents the real-time dynamic behaviour. This novel methodology has combined the merit of real-time simulation and straightforward finite element visual effect.

Dynamic Model and Impact Responses to
Road ExcitationUS

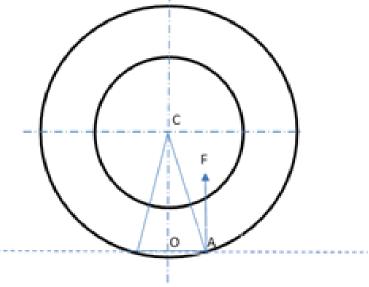

Fig. 1. Road impact on rolling wheel

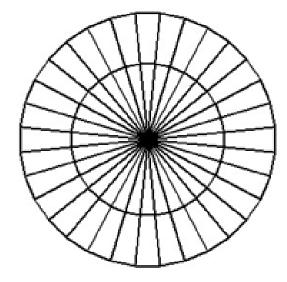

Fig. 2. Finite Element Wheel Model

During fast rolling, the velocity of contact A is significant, and the edge of contact receives an impact from the ground. This impact is continuously happening to the circumference of the tyre.

Dynamic Model and Impact Responses to Road Excitation

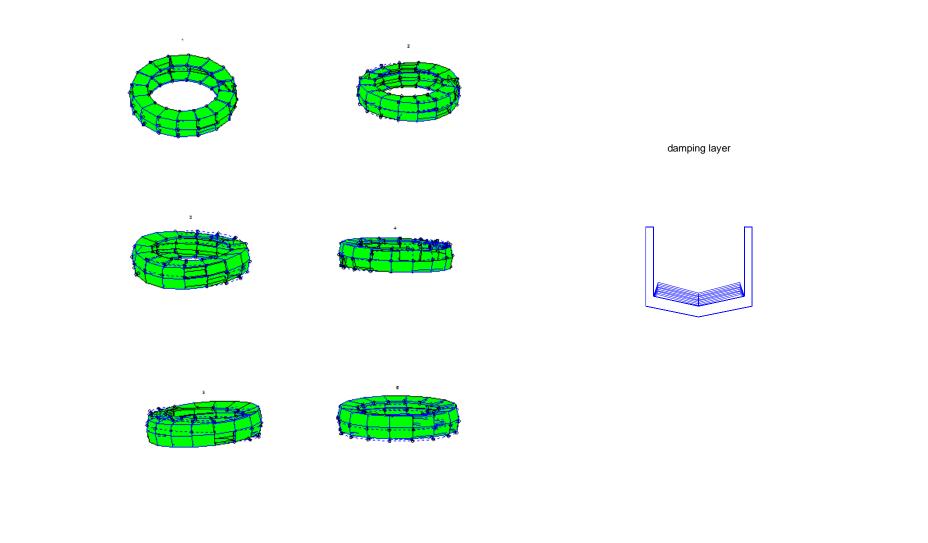

With *N* degrees of freedom, the dynamics of the model is governed by the equation of motion

$$[m]\{\ddot{z}\} + [c]\{\dot{z}\} + [k]\{z\} = \{u(t)\}$$
(1)

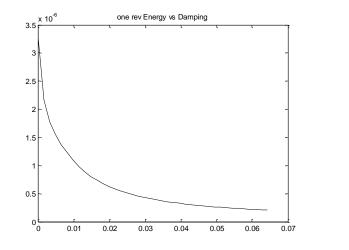

where $[m]_{N\times N}$, $[c]_{N\times N}$, $[k]_{N\times N}$, $\{z\}_{N\times 1}$, $\{u(t)\}_{N\times 1}$ are the mass matrix, damping matrix, stiffness matrix, displacement vector and external force vector, respectively

□ A finite element model is combined into the graphical dynamic simulation for visualizing vehicle wheel's response to road excitation.

□ Real time dynamic behaviour of the wheel to continuous impacts from the road during rolling is displayed.

The calculation result has indicated that the vibration which generates noise can be attenuated by increasing the damping in the wheel structure.

□ This proposed modelling and simulation have improved the understanding of wheel dynamics and can be used for environment friendly wheel design and development.

Thank you
